Abstract. In this paper the authors publish own experimental results of examination of low-alloyed cast steel STN 42 2707 fatigue properties (near-threshold regime of fatigue crack propagation for rates from \( \frac{da}{dN} = 5.6 \times 10^{-9} \text{m.cycle}^{-1} \) to \( \frac{da}{dN} = 10^{-12} \text{m.cycle}^{-1} \) and \( K_{\text{ath}} \) at \( \frac{da}{dN} = 10^{-12} \text{m.cycle}^{-1} \) initial state and after long-term heating (\( T = 400 \degree C, t = 4000 \text{ hours} \approx 167 \text{ days} \)) obtained at high-frequency loading (\( f \approx 20 \text{ kHz}, T \approx 20 \pm 5 \degree C, R = -1 \)). The long-term heating of material caused decrease of \( K_{\text{ath}} \) and increase of fatigue crack growth rate in the near-threshold regime; then worse of low-alloyed cast steel STN 42 2707 fatigue properties.

Key words– cast steel STN 42 2707, long-term heating, fatigue properties, \( K_{\text{ath}}, \frac{da}{dN} = f(K_a) \)

1. Introduction

Fatigue is a predominating fracture mode of components and constructions. Therefore, its prevention is a fundamental design criterion (BOKŮVKA O. et al. 2002, ULEWICZ R., MAZUR M. 2013). Lifetime of components or constructions (number of cycles \( N \)) contains number of cycles necessary for fatigue crack nucleation \( N_i \) and number of cycles for crack propagation \( N_s \). Components or constructions in terms of their resistance to fatigue failure can be evaluated by two methods; that is according to total lifetime (number of cycles \( N \), where \( N = N_i + N_s \)) or according to fatigue crack propagation with respect to laws of fracture mechanics (according to number of cycles necessary for crack propagation \( N_s \)) (TRŠKO L. et al. 2013, SKOČOVSKÝ P. et al. 2015).Evaluation of components and constructions resistance according to fatigue crack propagation describes well the real state, because the most of operation fractures is caused by fatigue crack growth from defects of different character. Amplitude of stress intensity factor \( K_a \) is the determining characteristic for describing fatigue crack propagation. In this case for evaluation of material fatigue properties is used experimentally obtained fatigue crack growth curve that is dependenton the rate of fatigue crack growth \( \frac{da}{dN} \) on the amplitude of stress intensity factor \( K_a \) and where the \( K_{\text{ath}} \) is basic threshold
value of amplitude of stress intensity factor $K_a$. In this curve there can be observed the near-threshold regime $(da/dN < 10^{-9} \text{ m.cycles}^{-1})$, mid-growth rate regime $(da/dN = 10^{-9} \text{ m.cycles}^{-1} \div 10^{-6} \text{ m.cycles}^{-1})$ and high-growth rate regime $(da/dN > 10^{-6} \text{ m.cycles}^{-1})$. The behaviour in the near-threshold regime is very influenced by structure, environment, value of $\sigma_m$, mechanical properties incl. toughness temperature and value of asymmetry coefficient $R$ (KUNZ L. 2003, RITCHIE R. O. 1981, BOKŮVKA O. et al. 2015).

Cast steels are very important group of construction materials. With regard to the chemical composition and structure, in principle, there are no differences from wrought steel. However, in cast steel-casting defects (buckles, shrinkages, cavities, blowholes and so on) resulting from casting procedure are observed (LETKO I. et al. 2002, SKOČOVSKÝ P. et al. 2000). These defects are preferred places for the fatigue crack growth (LETKO I. et al. 2002, KLESNIL M., LUKÁŠ P. 1975, HURTALOVÁ L. et al. 2013).

In this paper the authors publish own experimental results of examination of low-alloyed cast steel STN 42 2707 fatigue properties (near-threshold regime incl. $K_{ath}$), initial state and after long-term heating, obtained at high-frequency loading $(f = 20 \text{ kHz}, T = 20 \pm 5 \text{ °C}, R = -1)$.

2. Experimental part

The experimental work, quantitative chemical analysis, optical light microscopy, tensile tests and fatigue tests were carried out on two different states (initial and after long-term heating) of low-alloyed cast steel STN 42 2707. Chemical analysis was performed by the emission spectrometry on an ICP (JY 385) emission spectrometer using a fast recording system Image. A light metallographic microscope AXIO Imager A1m was used for metallography analysis. Tensile tests were carried out on a ZWICK Z050 testing machine at ambient temperature of $T = 20 \pm 5 \text{ °C}$, with the loading range in interval $F = 0 \div 20 \text{kN}$ and the strain rate $\varepsilon_m = 10^3 \text{s}^{-1}$. Round cross-section specimens were used; the shape and dimensions of the test specimens met the requirements of EN 10002-1 standard (5 specimens were used). Fatigue tests were carried out at high-frequency sinusoidal cyclic tension-compression loading $(f = 20 \text{ kHz}, T = 20 \pm 5 \text{ °C}, R = -1)$, cooled by distilled water with anticorrosive inhibitor and with the use of high-frequency loading equipment KAUP-ZU Žilina (BOKŮVKA O. et al. 2015, PUŠKÁR A. et al. 1987, TRŠKO L. et al. 2016).

\[ K_a = \sigma_a \left( \frac{\pi a}{W} \right)^{1/2} \text{ MPa.m}^{1/2} \]  (1)

in which $\sigma_a$ is stress amplitude (MPa), $a$ is the half crack length (m) and $W$ is the specimen width (m), (BOKŮVKA O. et al. 2015, PUŠKÁR A. et al. 1987, TRŠKO L. et al. 2016). The fatigue crack growth rate $da/dN = f(K_a)$ in the area from $da/dN = 5.6 \times 10^{-9} \text{ m.cycles}^{-1}$ to $da/dN = 10^{-12} \text{ m.cycles}^{-1}$ and the value of $K_{ath}$ was determined at $da/dN = 10^{-12} \text{ m.cycles}^{-1}$; four specimens of initial state of low-alloyed cast iron and the four specimens after long-term heating $(T = 400 \text{ °C}, t = 4000 \text{ hours} \approx 167 \text{ days})$ in the furnace with protective atmosphere were used.

3. Results and discussions

The results of quantitative chemical analysis (chemical composition), tensile tests (yield point $R_{p0,2}$ tensile strength $R_m$, elongation $A_5$, reduction of area $Z$, toughness KCV$^{+23}$), optical light microscopy (microstructure) and high-frequency fatigue tests $(da/dN =
f(Ka, K_a) are shown in Table 1, Table 2, Table 3 and on the Fig. 2 and Fig. 3.

Source: own study

The chemical composition and mechanical properties of tested material, Table 1, 2 correspond with STN 42 2707 standard. The microstructure (Fig. 2) was created by ferrite and perlite and is characteristic for cast steel.

The obtained results about fatigue resistance of low-alloyed cast steel STN 42 2707 are shown in Table 3 and on the Fig. 3. The basic amplitudes of stress intensity factor K_a were K_a = 5.14 MPa.m^{1/2} (initial state A) and K_a = 4.46 MPa.m^{1/2} (state after long-term heating, B); decrease (B) against (A) state is cca 13.2 %. We can calculate the critical size of crack a_c (permissible size of defect) with using equation (2), where

\[
a_c = \frac{1}{\pi} \left( \frac{K_a}{\sigma_s} \right)^2 m
\]

K_a is basic threshold value of amplitude of stress intensity factor (MPa.m^{1/2}) and σ_s the safe stress (MPa); σ_s = 80 MPa and is valid in the power industry for water pumps design. The critical size of defect is a_c = 1.31 mm (for initial state, A) and a_c = 0.98 mm (for state after long-term heating, B); decrease of this value for heat treated state against value for initial state is cca 25.2 %. These facts correspond with works (BOKÚVKA O. et al. 2002, BOKÚVKA O. et al. 2015). The value of K_a for initial state (Table 3) was K_a = 5.14 MPa.m^{1/2}. The authors (RŮŽIČKOVÁ M. et al. 1999) in their study based on their own results (19 th wrought steels with R_m from R_m = 360 MPa to R_m = 1820 MPa) suggested equation for K_a calculation (3),

\[
K_{a,th} = -0.0052 R_m + 8.5906 \text{ MPa.m}^{1/2}
\]

where R_m is tensile strength [MPa]. This equation is valid in the region from R_m ≈ 360 MPa to R_m ≈ 1040
MPa, after \( R_m \approx 1040 \text{ MPa} \) the \( K_{\text{ath}} \) is constant, \( K_{\text{ath}} = 3.21 \text{ MPa.m}^{1/2} \). With using equation (3) the value of \( K_{\text{ath}} = 6.17 \text{ MPa.m}^{1/2} \). The experimentally determined value of \( K_{\text{ath}} \) in the case of low-alloyed cast steel STN 42 2707 is lower.

The obtained results mentioned above confirm the conclusions about a considerable influence of different factors (e.g., structure, temperature, mechanical properties incl. toughness) on the fatigue resistance of structural materials in the near-threshold regime (TRŠKO L. et al. 2013, RITCHIE R. O. 1981, BOKŮVKA O. et al. 2015).

The results (Fig. 3) after \( da/dN = 10^{-10} \text{ m.cycle}^{-1} \) are for the both state (initial and state after long-term heating), is practically the same. It corresponds with works (KUNZ L. 2003, RITCHIE R. O. 1981, BOKŮVKA O. et al. 2015, TRŠKO L. et al. 2016) which stated small influence of structure, temperature, mechanical properties incl. toughness, \( \sigma_m \), and environment on the dependence of rate of fatigue crack growth \( da/dN \) vs. amplitude of stress intensity factor \( K_a \) in the mid-growth rate regime.

With regard to the results, it can be assumed that aging is the reason of fatigue resistance decrease. This effect is observed very often in the mild steels. The aging is the reason for changes of material strength and deformation properties. The tensile strength, yield point, hardness increase but, on the other hand, the elongation and toughness decrease. The size of plastic zone on the crack tip decrease. With regard to this fact, the retardation effect against fatigue crack growth decrease and therefore decrease the value of \( K_{\text{ath}} \) (Pišek F. et al. 1975).

4. Conclusions

With reference to the experimental results carried out at high-frequency loading (\( f = 20 \text{ kHz}, T = 20 \pm 5 \text{ °C}, \ R = -1 \)) the following can be summed up:

- in the low-alloyed cast steel STN 42 2707 was recorded negative influence of long-term heating (\( T = 400 \text{ °C}, t = 167 \text{ days} \)) on her fatigue resistance in the near-threshold regime;
- the basic threshold value amplitude of stress intensity factor \( K_{\text{ath}} \) due to long-term heating decrease cca 13.2 % (initial state \( K_{\text{ath}} = 5.14 \text{ MPa.m}^{1/2} \); state after long-term heating, \( K_{\text{ath}} = 4.46 \text{ MPa.m}^{1/2} \));
- the critical defect size decrease cca 25.2 % (initial state, \( a_c = 1.31 \text{ mm} \); state after long-term heating, \( a_c = 0.98 \text{ mm} \));
- in the mid-growth regime of \( da/dN = f(K_a) \) curve was not recorded differences in fatigue behavior;
- these facts must be taken in consideration with reference to reliability and safety when designing the structural elements.
